

Digital Signal Route Determination Method

Field of the Invention:

The invention relates to digital signal routing and more
5 particularly to a method of choosing a Digital or Datalink Service
Provider (DSP) based on factors unique to the user.

Background Of the Invention

Currently in the aviation industry, the state of the art for providing
10 a DSP consists of installing software in various pieces of equipment
that sends the message solely to the service provider who holds the
contract for that user. All messages are then sent through that provider
regardless of any priorities associated with the message and without
considering any other competing service that might be available. This
15 software normally resides in a Communications Management Unit
(CMU) in aircraft and in some type of communications router for ground
side operations. The software directs all messages to be sent over a
single digital service provider network. The digital signal routing
decisions are made almost solely on the basis of which Digital Service
20 Provider (DSP) a user chooses to contract with as shown in Fig. 1.

Historically, this has been sufficient since there was minimal overlap in services, limited competition, and a relatively limited number of digital messages. All of these paradigms are changing and the limited number of digital service providers is increasing. As the number of messages
5 increases, the competition will increase. This will cause a definite change in the availability of choices. Not only will there be additional competitors, but eventually the two major DSPs will have significant overlap of capabilities and service, certainly from a geographic perspective. This overlap, as well as the introduction of new providers,
10 will enable a dramatic increase in competition for those DSPs that can distinguish their offering and provide analysis of information for the user, leading to various user advantages at any given time. This increase in competition creates a need for real time or near-real time ability to choose or change the route by which a digital message travels
15 to maximize the economic advantage of one route over another. Another failing of the current system is that it does not consider that some messages require special handling. It is possible that a given user may place a higher value on security or latency or even the guaranteed integrity of the message rather than mere expediency.

20 The present state of the art is the ARINC system located at <http://www.dominium.com/message.html> which discloses a system that only uses a single provider and is not prioritized by any factors. The

system teaches a ground transportation product and uses one network unless it is out of range and then allows the user to choose a satellite media if the message is a priority. It can be programmed to default to this option for certain messages if desired. Neither of these methods
5 continually considers several factors and multiple routes when available before choosing the most appropriate route based on the customer's criteria.

U.S. Patent No. 5,570,417 discloses a system that is focused on fixed, ground-based telecommunications infrastructure. In addition, it
10 assumes a model whereby the rate structures are fixed, based on a predetermined route. It also assumes a fixed initiation and receiving point as opposed to one or more of those points being dynamic.

U.S. Patent No. 5,661,792 also discloses a fixed, ground-based telecommunications infrastructure. As with Patent No. 5,570,417, it
15 assumes a model whereby the rate structures are fixed, based on a predetermined route. It considers reliability but only from the perspective that should the primary carrier be unavailable, the database will identify an alternate carrier.

To date, there have been no new proposed solutions to deal with
20 this problem. In the current aeronautical business model as shown in Fig. 1, current user discussions continue to focus on negotiating optimal rates with one DSP. If a user contracts with only one DSP and then

uses another DSP's service, due to lack of regional service for example, the existing structure assumes the receiving DSP will deliver the message and bill the DSP which has a contract with the user. The DSP holding a contract with the specific customer will then turn around
5 and bill the customer for the service along with additional handling charges. Even though some users contract with more than one DSP, this is done primarily with the intent to use a specific DSP within specific regions of the world. With software installed in the CMU when an aircraft is purchased or when a contract is negotiated, there is no way
10 to effect economics, security, latency or quality on a real-time basis. A user is forced to use the sole source message route a DSP provides.

There are some existing digital service communications (though not in aviation) that have introduced some portion of economics into this problem. These existing ground solutions typically hold a message until
15 lower cost service is available. In actuality, this method only holds the message until contracted service is available which avoids the double fee charging as discussed above. The basis of the economic advantage is that holding the message until contracted service is available will ensure lower cost service.

20 However, none of the prior art devices introduce multiple priorities into the decision making process, enabling the user, or initiator, to gain this significant benefit.

SUMMARY OF THE INVENTION

My invention defines a method of providing the user with the ability to choose various digital message routes based on his particular needs at any given time. My method for Digital Signal Route Determination (DSRD) addresses the short comings of the prior art by installation of overlay software anywhere a message is initiated, whether that is on a vehicle, user initiation facility, or government control facility. Overlay software is envisioned simply as software added to existing equipment that does not interfere with current processing in any way, and only acts to filter the digital message to understand its unique routing needs and subsequently to direct the message to the appropriate route. This software is capable of choosing:

- the most economic route;
- the most secure route if required;
- the fastest (latency) route if required; and/or
- the route that affords the highest integrity.

An aspect of this invention is that it combines multiple priorities, sorts the data according to programmed information from the customer, and makes a decision based on that information. In addition, this

information can be updated near or near-real time as required depending on the application.

A primary object of the present invention is to provide a user with a choice of a DSP provider based on criteria and priorities selected by
5 the user.

Another object of the present invention is to provide a user with a cost effective selection process for a DSP provider.

Yet another object of the present invention is to enable a level of competition, leveraging growth in overlapping services, that does not
10 exist today.

A primary advantage of the present invention is that the invention can be sold as a service to reduce cost for a user, increase the user's efficiency, and enhance security. It can be used by any participant in the aerospace community that sends or receives digital messages.

15 Another advantage of the present invention is the ability of the user to choose a DSP depending on the user's criteria.

Yet another advantage of the present invention is that the user can prioritize his criteria for the appropriate output from the invention.

Other objects, advantages and novel features, and further scope
20 of applicability of the present invention will be set forth in part in the detailed description to follow, taken in conjunction with the accompanying drawings, and in part will become apparent to those

skilled in the art upon examination of the following, or may be learned by practice of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

5 The accompanying drawings, which are incorporated into and form a part of the specification, depict several illustrative of the present invention and, together with the description, serve to explain the principles of the invention. The drawings are only for the purpose of illustrating a preferred embodiment of the invention and are not to be
10 construed as limiting the invention. In the drawings:

Fig. 1 shows the existing prior art model for digital signal routing;

Fig. 2 shows the method for the present invention;

Fig. 3 depicts the use of overlay software in accordance with an aspect of my invention;

15 Fig. 4 demonstrates the concept of the preferred decision making process; and

Fig. 5 shows an example of the preferred overlay process in accordance with my invention.

DETAILED DESCRIPTION

20

The present invention leverages competing digital communications services in a way that will allow benefit to incur to the

user. The invention identifies various priorities associated with a given digital message, tags this priority to the message, and subsequently uses this information to control the media choice and/or the route within a media. By enabling a priority system, the user will be able to effect the economics of sending a message, or increase the security, increase the speed of delivery, or guarantee a certain level of quality/integrity for the digital message. Each of these factors are prioritized and chosen by the user.

The method in accordance with my invention of provides the user with the ability to choose various digital routes based on his particular needs at any given time. Fig. 2 graphically portrays the general concept of my invention, which can be compared to the existing model described in Fig. 1. To accomplish the decision making required, proprietary software comprising simple look-up tables and key algorithms defined by the customer is introduced. "Overlay software" is the name given to this proprietary software installed at any site where a communication is initiated. This software contains the commands and algorithms needed to choose the appropriate media route. "Tagged" is the term used to define the process of adding software coding to an individual message that defines priority of a specific message. Once a message is Tagged, the Overlay software can determine the most appropriate route. (see Figure 3). My method for digital signal route

determination addresses the problems of the past by installation of Overlay software anywhere a message is initiated, whether that is on a vehicle, user initiation facility, or government control facility. Fig. 4 demonstrates how the sequence will work. This Overlay software is

5 capable of choosing:

the most economic route (**step 1**);

the fastest (latency) route if required (**step 2**);

the most secure route if required (**step 3**); and/or

the route that affords the highest integrity (**step 4**).

10 Thus the Overlay software advantageously comprises one or more of look up tables, algorithmic calculation and real-time information on cost, available DSP routes, and DSP route status information. Further, the real-time information is advantageously updated, as by time based updates or by querying a DSP provided.

15 For message prioritization, my method allows the user to leverage all existing routes, and through unique algorithms, choose the most appropriate route based on a pre-determined hierarchy of needs (**see steps 1-4 in Fig. 4**). This hierarchy of needs (**steps 1-4**) can be adjusted for each potential user of my DSRD method. As a simplistic
20 example, each of the four criteria (**steps 1-4**) might be weighted using a scale of 1–10, with 1 being of minimal importance and 10 being most important. Each user then defines the priority of each criteria that user

wants to assign to each type of message. The number and complexity of prioritization are primarily dependent on two factors: first, the complexity and quantity of different messages the user needs to send; and, second, on the number of available routes the software will be able to choose from. The actual weighting of priorities is negotiated with each customer according to their unique needs. The step of closing the DSP route could be performed at a vehicle, a user installation facility, or a government control facility.

Fig. 5 is offered as an example of how the process will work. In this example the “customer” has defined cost as the highest priority. Each message type will preferably be Tagged, step 10, when it is created so that the Overlay software, steps 20-50, can determine the priorities that are applicable and then choose an appropriate route, step 60. The Tagging of a message, step 10, can be accomplished in a variety of ways. These include a simple manual input from the user, automatically based on where it originates or how it is created. The updating of the information used in the tables and algorithms is also shown, step 80.

In real use, the Overlay software for my DSRD method will use a combination of lookup tables and real or near-real time information on cost, available routes, and route status updates from the DSPs to determine which route is most appropriate for any given message (see

Figs. 3, 4 & 5). Updates to rates and/or system status can be provided in various ways, from a time-based method to an aircraft power-up method to a real time, in-air update as a message is sent (not shown). Primarily the user community and the DSPs will determine the update
5 need as the number of digital messages and competition increases, and integrity and latency begin to have added impact to the user. The model is defined in such a way as to evolve to accommodate any or all of the potential update solutions, as they are needed.

A time-based update assumes that changes will occur on a
10 predetermined, scheduled basis. For example, monthly each vehicle participating in the use of my DSRD method would be provided with the latest rates and status of the actual system. For example, a Ground Earth Station (GES) might be down for repair or a new one may have come on-line. On the other end of the update spectrum, a vehicle
15 would query each provider to determine the best instantaneous rate given the aircraft position when it desires to send a message. In this case, the method would determine the most appropriate route based on the newly up-linked or downloaded rate structure. This method would also enable a simplified auction for service, i.e. the user could allow
20 each provider to bid for the service in near real time.

If desired, for certain messages, the user could establish a predetermined rate. If this rate were not met, the message would not

be sent until the vehicle arrived at a location where the service could be provided at the predetermined cost. An intermediate solution might function in a manner such that when the vehicle powers up, it would initiate a status message querying the system to compare current
5 information on-board with the master database. If the master database detects out of date rates it would automatically download the current rate structure.

Included in my method is an accounting infrastructure whereby the DSPs would bill the system controller who would then bill the
10 respective users on a periodic basis (or as negotiated). Part of the purpose of the Overlay software is to count the number and addresses of sent messages to enable verification of service use (see step 70 in Fig. 5). The only way this type of accounting is accomplished today is to have the operator manually note the time, date, and address of a
15 message as it is sent. There are few vehicle operations that have the luxury of allocating the time to track accurately digital messages. Certainly in the future, this will become even less likely as numerous status messages are envisioned to be sent automatically. My DSRD method not only provides for consolidated billing, but will also ensure
20 accuracy by enabling user tracking even though it is likely that traffic will be sent over multiple DSP networks.

It is possible to take one priority such as economics and choose message routing based entirely upon this single criterion. The method of my invention would still work, just not provide as many advantages to the user. From the same perspective, it is possible to have two criteria
5 or three without all four and still be useful.

My DSRD method also has potential uses outside of the aviation industry. Literally, any wireless communication usage could benefit from my invention as a way to enhance economics, latency, security, integrity or combinations of these criteria. The invention is applicable
10 wherever digital messages or information are sent where there is more than one potential route that the message/information can be sent over and each route potentially has a different cost. An example might be the need to identify a hierarchy for messages sent on a battlefield. The present invention can be used for any digital message transmitted to
15 another party, such as cell phones, existing telephone lines, other transportation industries (bus, rail, truck, taxi, etc.). There is no question that latency and security are key elements of the modern battle. Another example might be ground transportation networks that have a business need to minimize cost while still considering critical
20 messages that will affect efficiency.

The method of my invention can be further illustrated by considering that on a flight from New York to Frankfurt, Germany, an

airliner receives a digital message requesting a deviation from their planned route of flight to avoid an aircraft traveling from Miami to Boston. Since the potential for a midair collision would exist if neither
airliner makes a change to their route of flight, this becomes a priority
5 message where speed is most important. The proprietary software would tag the message as a speed or latency priority and subsequently send the message over the most expedient route (the example in Fig. 5 is applicable with the exception that cost and latency flip flop in importance). In this example, both airliners are inside of line-of-site
10 range allowing the use of a Very High Frequency (VHF) message. For this reason, the proprietary software chooses to send the message over a VHF route. Two SATCOM networks are available at comparable delivery speeds but at greater cost. The message is sent acknowledging receipt of the original request and notifying Air Traffic
15 Control (ATC) that the air liners will make the requested deviation. At the same time that the message is sent, the proprietary software stores the time, location, length of message, and routing for future accounting purposes. When ATC confirms that the transoceanic airliner will deviate, they also request notification of any significant weather
20 encountered by the airliner. Since the airliners acknowledgment of the message is no longer a priority, the proprietary software tags the message with the appropriate low priority (the example in Fig. 5 is

appropriate but now cost again becomes the priority since time is no longer an issue). The proprietary software then sends the message over a SATCOM network because it is the only available route (as the New York to Frankfurt plane has continued eastward during the example, it has moved out of not only VHF coverage but also the second SATCOM coverage area). In this case, even though cost was the priority there was only one route available for use so the Overlay software chose that route. As in the first response, the proprietary software stores location, time, length of message, and route for future accounting purposes.

Although the invention has been described in detail with particular reference to these preferred embodiments, other embodiments can achieve the same results. Variations and modifications of the present invention will be obvious to those skilled in the art and it is intended to cover in the appended claims all such modifications and equivalents.
